Usability Analysis with Markov Models

PAUL CAIRNS, MATTHEW JONES and HAROLD THIMBLEBY
Middlesex University, London

How hard do users find interactive devices to use to achieve their goals, and how can we get this information early enough to influence design?

We show that Markov modelling can obtain suitable measures, and we provide formulas that can be used for a large class of systems. We analyse and consider alternative designs for various real examples. We introduce a "knowledge/usability graph," which shows the impact of even a small amount of knowledge for the user, and the extent to which designers' knowledge may bias their views of usability.

Markov models can be built into design tools, and can therefore be made very convenient for designers to utilise. One would hope that in the future, design tools would include such mathematical analysis, and no new design skills would be required to evaluate devices.

A particular concern of this paper is to make the approach accessible. Complete program code and all the underlying mathematics are provided in appendices to enable others to replicate and test all results shown.

Categories and Subject Descriptors: B.8.2 [**Performance and reliability**]: Performance Analysis and Design Aids; D.2.2 [**Software engineering**]: Design Tools and Techniques—*User Interfaces*; H.1.2 [**Models and principles**]: User/Machine Systems; H.5.2 [**Information interfaces and presentation**]: User interfaces (D.2.2, H.1.2, I.3.6)—*Theory and methods*

General Terms: Design, Human Factors, Performance

Additional Key Words and Phrases: Markov Models, usability analysis.

1. INTRODUCTION

How can products be designed to be more usable? The usual answer to this question is that usability depends on the match between the product and the users under the particular constraints of the environment and tasks being performed with the product. The problem is that usability, seen like this, depends on the world when the product is used (or tested) *not* when it is designed. So if we want to design better products, foresight has to be used. Foresight can be based on scenarios and case histories from previous product evaluations; sometimes foresight can be focused by general psychological or socio-technical knowledge. Whatever, design for usability

requires considerable expertise and commitment to usability, neither of which is conventionally nor realistically available in the crucial early stages of technical design. Often one therefore seeks improvements in usability *after* the initial stages of design — once a prototype exists — for example in improved manuals. Yet good manuals cannot be written for bad systems!

In this paper, we are concerned with methods to improve usability that can be employed as early as possible in the design process. They complement, but do not replace conventional user centred design approaches. Indeed if technicians employ our methods, they would be much more open to usability engineering issues.

1.1 A dream...

In a dream, you have been given the job of developing a large Scottish estate to improve access for various groups. The estate has forest, mountain, rivers, and the usual Scottish flora and fauna.

Since the estate is easily accessible, one group of users will be families. For this group you will need to establish clearly-signed trails, mostly level, and provide guidance such as a typical ramble's duration. Most families will like to choose between 1 hour, 2 hour or 3 hour walks.

Another group is the local running club. This group wants a track that is a particular length, and they would like 5km. They like to run as fast as they can, and they want to know how fast they go: so for them, the distance matters (so they can work out their speeds), rather than a typical time for a ramble, which is what the families want.

And the third group is the climbers, who want to take advantage of the excellent rock faces for abseiling. The estate has two cliffs, one 20m high, the other 65m high. Part of your job will be to ensure there is proper access to these sites, and to ensure there are facilities (e.g., for securing ropes at the top).

Well, our dream is getting so interesting we are drifting from the purpose of this paper! The analogy is, of course, that as usability engineers we have to design systems for different sorts of user, for different sorts of task, and so on. But in our dream, every sort of decision could be based to some extent on facts: that families take so many hours on a trail; that the running track is so long; that the rocks are so high. The contrast is that the usability engineer has practically no hard data to go on. System engineers have left usability engineers bereft of data.

This paper proposes a system model that can provide hard data about certain sorts of interactive system. Moreover it is very flexible. It can be used to provide objective facts like the 5km distance the runners need, or it can be used to provide estimates like the 2 hours the families need. And it can be modified with experience — when we learn that families spend a lot of time playing by the water — we can easily modify the model to accommodate empirical data, so that further analysis is more realistic. We can assume users behave randomly, we can assume they are experts, or we can take any position along the spectrum.

There are, however, caveats to using numbers in usability engineering. Just as precisely measuring distance in a Scottish estate won't tell you how long a family will take or even how long a runner will take, rigorous measures must be related in the appropriate way to the intended tasks. In this paper, we hint at some of the possibilities, but mostly we concentrate on getting accurate numbers. For

example, one interface we discuss is a combination lock. Clearly, some users (those with authority or permission) should find the lock reasonably easy; other users (those without authority) should find the lock hard. Our model will not address that issue, but it will say quite clearly how easy or how hard the lock is under various circumstances. We can also accommodate empirical information about user's behaviour and use this to inform trade-offs for modified designs.

More specifically, our approach is based on Markov models. These have a solid mathematical foundation, and one point of this paper is to show that such mathematical methods can be recruited to the design process very effectively. In particular, they can be used very early in the design process, as easily as, say, cardboard or polystyrene prototype interfaces.

In addition to providing numerical results, Markov models have a useful property: real systems (e.g., mobile phones) can be modelled effectively in their entirety, with no need to take 'abstract,' simplifying or approximate approaches.[1] A Markov model can also be used to build the hardware or to run user interface simulations. They are both powerful enough to be complete, and convenient enough to support detailed analysis. Because of these properties, unlike almost all other 'formal methods' for user interface analysis, our approach can be built into design tools. There is no need for the design tool to 'understand' how to abstract user interface properties, or to understand how to perform formal specification; conversely, there is no need for the designer to be mathematically sophisticated. Markov models are complete, and any design tool capable of animating a user interface in principle has an exact model available, where our approach can be used directly.

A common criticism of formal methods, and indeed of many other usability engineering methods is that they depend for their success to an excessive degree on craft knowledge [18]. That is, there are specialised skills tacit in many approaches, and other practitioners therefore find them harder to deploy with good results than their proponents. In contrast, Markov models can be exploited in user interface analysis with no craft knowledge. Obviously, craft knowledge can be exploited if it is available, but, for instance, all the results exhibited in this paper can be fully automated. A design tool could, for example, be asked to produce the equivalent of, say, Figure 4 for a working design, and it could do so with no further direction.

In support of these claims, Appendix A provides the code that was used to calculate all examples used in this paper; further, a published paper, [26], explains and provides *complete* code that can be used for *all* of: Markov model analysis, run user interfaces, generate user manuals, collect and analyse empirical data from use, and analyse alternate designs.

1.2 Reality...

Many simple push-button devices have awkward features:

—*Canon EOS500 automatic SLR camera.* This camera has a control knob that selects the main state (off, aperture priority, normal ...), and various buttons for controlling details of the selected state (e.g., exposure time). Most states have time-outs and only stay operational for a few seconds, presumably so that

[1]There are many *well defined* features of an interface that Markov models ignore, such as their colour; but such features are easily, if not mechanically, identified.

the user does not accidentally use an inappropriate exposure, as photographic conditions can change in a few seconds. However, the main control knob has no time-outs, and therefore it is very easy for the user to leave the camera in any of its 13 on states. There is also a timer state, which delays the shutter by ten seconds. This state itself has no time-out, and will still affect the operation of the camera even months later — to the surprise of a user who wants to take an immediate photograph! How should the time-outs be allocated?

—*Pioneer KEH-P7600R car radio.* This radio has multiple menu systems. Some features cannot be used without glancing down at to see the feedback on the front panel of the radio (the number of button presses to change certain modes is not fixed, but depends on previous actions). The more button presses are required to operate it, the longer the driver is distracted from safe driving [27].

—*Nokia 2110 mobile phone.* This mobile phone has almost 100 functions, many accessed by a menu system, and some by other means. Some functions are very easy to access, though some are harder. Any functions not accessed via the menu must be memorised by the user; for example, it is very difficult to find out how to set "keypad lock" if one does not already know how to do it. How should the menu and function allocations be designed? We examine the Nokia phone in Section 4.4.

—*Panasonic Genius microwave cooker* ([19; 20; 21]). This cooker has a digital display capable of showing 0 to 9999. Its clock is twelve hour, so very many numerals (e.g., 00:30, 10:73, 15:45, 67:43) it can display are invalid times. Our empirical tests with a simulation suggested that half the user population would get stuck if attempting to set the time in the afternoon: they would set it to an 'invalid' time and then not know what to do. The *Genius* is an old model, and a more recent (June 1992) model is exactly the same (so far as we can tell), and therefore has exactly the same usability problems — except that its user manual now describes the problem. Presumably the manufacturer made many microchips with the original design, and cannot afford to correct the fault. We examine the *Genius* in section 4.5.

What could the designers have done to foresee or avoid these problems *before* there had been any investment in fabrication? Conventional human factors evaluation relies on some form of 'product' the very existence of which might make changing the design harder or more costly. Thus it is crucial to bring usability concerns right to the earliest stages of design. This suggests employing mathematical models.

2. MATHEMATICAL METHODS

We argue what is needed is an analytic approach to assessing usability which does not depend on the existence of a concrete prototype, and which is not susceptible to (for instance) cultural assumptions that might accidentally be shared between designers and particular test user groups.

Mathematical methods applied to user interface design are important, but they may seem minor compared to the 'real task' of designing a system that suggests and supports appropriate, task-relevant actions. This is a misconception: the real

task of design includes more than just making a system suggest and support task-relevant actions and so forth. A design method must succeed reliably, completely, and consistently (to chosen criteria): in short, it must be trustworthy. Interactive systems are typically very complex, and beyond almost everyone's ability to understand them — why else are video recorders still difficult to use? (either because users can't cope, or because designers can't cope) — so some sort of 'mental leverage' is required. This is exactly what mathematics is for. Without a mathematical basis, except by lucky chance (or a good demonstration), interactive systems merely give the temporary semblance of being easy to use.

The problem with mathematical models is that their use often requires mathematical skill. Many devices are complex, and it is often very difficult to model them accurately, even though it may be — or may have been — easy to program them adequately (e.g., in a multimedia development system) to simulate them for coventional usability studies. Many multimedia development systems and device programming systems are so low level, that it is very hard to know what has actually been programmed! Indeed, Newman and Lamming [13] suggest that often the only satisfactory means of description is to build a prototype. Unfortunately, people build prototypes and lose track of the design specification. This says more about the poor state-of-the-art in user interface design systems than the supposed limitations of formal methods.

The main advantages of mathematical methods include:

—There can be high certainty in those aspects of the design where analytic methods are applicable.

—Analytic methods have good cost-performance: low cost (particularly once the appropriate mathematical model has been determined) and high performance, that is, their generality. This is a standard claim for mathematics; this paper substantiates the claim for user interface design in particular.

—Assumptions are generally explicit, or become explicit: one has to make, for example, an explicit model of *either* a 12 or 24 hour clock — exactly the sort of assumption that with empirical usability studies might be lost in cultural assumptions (e.g., the designers and test subjects all happen to think in 24 hour models) and hence not be properly assessed.

—Relying on thorough empirical tests with users is unrealistic (a fast, tireless, diligent human working non-stop 12 hours a day would take a month to test just the four time setting buttons on a typical digital clock; and with any mistakes they'd take *far* longer). Mathematics is faster!

—It is convenient to do mathematical analysis in a package such as *Mathematica*, and this *simultaneously* allows us to simulate the device so it can be used — and can be subject to conventional usability evaluation studies also. Alternatively, mathematical analysis can be packaged inside design tools, such as simulation tools, and can then be made transparent (i.e., unobtrusive) to designers.

—A mathematical approach abstracts the complexity of devices. As we argue below (both in general and in particular), a mathematical approach is scalable.

—Conventional empirical design methods are easily misused (e.g., through poor experiment design) without anyone noticing; in contrast, a mathematical approach

can be automated, and even where it cannot be automated — or, rather, has not yet been automated — most people who don't understand it won't even be able to get far enough to make design mistakes!

—Finally, all the usual advantages of formal methods obtain, such as guarantees of safety properties for devices in safety-critical systems.

The mathematical approach used in this paper requires matrices, which represent Markov models of finite state machines (FSMs). Though finite state machines are a simplification of user interaction, their simplicity makes them a flexible tool. Further examples of their use can be found elsewhere [22; 25].

Push-button devices are an easy target for FSM representation because they can be understood as a set of states for which button presses are state transitions. However, by not constraining states of the model to internal states of the device, it is possible to examine other systems. For example, if states were equated with tasks and goals, different FSM could represent the same system as seen by a variety of users from novices through to experts, from families through to rock climbers. The available transitions would represent the knowledge of the user and even the purposes of the user.

Any model is not worth its salt unless it provides useful measures at a timely point in the design process. As with all formal representations, however simple, Markov models provide the facilities for measuring the model. And like all models, translating the results back to the thing modelled requires interpretation. The further the model is removed from the original, the more care must be taken in the interpretation. To avoid becoming entangled in difficult and ambiguous interpretations that are secondary to the methods being demonstrated, the examples in this paper steer away from tasks and goals and instead make direct mappings between between system states and model states.

2.1 Scalability of finite state machines

Finite state machines have the problem that the number of states for even modest systems is enormous. The complaint that FSMs are inadequate is like complaining that metres are an inadequate way of measuring the distance to the moon. They certainly would be if you had to draw each one. For clarity, we *have* drawn some FSMs, and shown the matrix representation of others in full. This is not technically necessary, and indeed gives a misleading impression of the paperwork needed for the approach. Fortunately, the actual size of the FSM is irrelevant to the formal mathematics. According to Shneiderman [17], it would be "a major contribution" to have scalable formal methods and automatic checking of user interface features: finite state machines (and Markov models) have this advantage when properly understood.

There is a body of opinion that finite state machines (FSMs) are inappropriate for realistic interactive systems (e.g., [10; 12; 14]). We do not dismiss them out of hand so readily, not least because they are simple, tractable, and — as this paper shows — insightful. This paper is also able to furnish *full* details of how it did so (one appendix provides all the necessary program code, another provides the underlying mathematics). The results described in this paper are therefore fully reproducible, and can be readily tested, extended or built on by others. The under-

lying representation we need is just a matrix, which is trivial to import or export into other analysis or design tools. More sophisticated methods would compromise the simplicity, reproducibility and transparency.

Antipathy arises because finite state machines are inappropriate for realistic simulation — including animation — of typical interactive systems. Finite state machines are extended in various *ad hoc* ways to handle many multimedia features that make device prototypes sufficiently realistic to be used for some sorts of usability studies. But to make this into a general argument against FSMs would be to confuse simulation for analysis, which is the present purpose.

Often formal methods are not used appropriately: for example, large FSMs can easily be constructed by Cartesian products and other operations from smaller FSMs,[2] or by using languages such as Esterel or Lustre [6]. A designer need never see a complete, explicit low-level definition (such as a diagram or a flat transition table). Indeed Halbwachs [6] shows that FSMs are very sensitive to small changes in the high-level definition, and therefore are unreasonable and unsuitable for explicit use in design — if they were used explicitly, "small changes" to a design would mean a complete rewrite of the FSM. Fortunately the mathematics works equally well, whether or not the FSM is of manageable size for manual methods. (For example, the Appendices, which underpin all the mathematics used in this paper, do not require the size of a FSM to be given.)

FSMs are described in elementary theory of computation books, and often covered briefly before moving on to the more powerful but still impractical Turing Machine. It is a standard result that FSMs are not very powerful computational devices. For example, FSMs cannot multiply binary numbers. But to understand these sorts of results as implying that FSMs are inadequate for defining user interfaces confuses a general result with any particular problem. True, FSMs cannot perform certain sorts of *arbitrary* calculation (those which require Turing Machines with infinite tapes), but for any particular problem, a large enough FSM can perform the calculation if it can be performed at all. This should be obvious: personal computers are widely thought to be 'as powerful as' Turing Machines, but, unlike Turing Machines, in reality they do not have infinite memory! Feynman [4] is one of the few authors to make this elementary point clear.

FSMs are often illustrated with simple diagrams (such as our Figure 3, below), which approach is clearly an impractical way of representing FSMs with many states. As our approach does not rely on diagrams in any way, the difficulty of drawing or understanding complex diagrams is irrelevant. Transition diagrams have problems with concurrency, such as how to represent several streams of user interaction at the same time, or how to support several users [13]. This, too, is a notational problem that FSMs do not have. FSMs are not transition *diagrams*.

Statecharts [7; 8] are a very good way of drawing suitably structured FSMs with more states but, again, as a visual representation they have problems with large specifications — and if Statecharts are an improvement and they *still* have problems, then detractors would obviously argue FSMs must be fundamentally flawed! Fortunately our approach to FSMs does not require drawing them.

[2]Indeed, the example in [12] of a supposedly "just manageable" system is the Cartesian product of trivial two state FSMs!

The situation with FSMs is analogous to machine code. All computers use machine code (or in the few cases that do not, they could do so in principle), but a computer programmer need never be concerned with machine code if they use high level programming languages. Indeed, high level programming languages are so much more convenient that it might often seem silly to be concerned with machine code. From this it would be a short, but misguided, step to assert that machine code is somehow inadequate for specifying, analysing or designing systems.

3. FROM FINITE STATE MACHINES TO MARKOV MODELS

This section introduces and justifies the use of Markov models in user interface design. Markov models are a standard mathematical technique (see Appendix B for references), and their value for modelling processes has been widely recognised — from describing models for existing systems [2] to developing test cases [28]. Our approach adds a new view of modelling not only internal processes but also external interaction, and shows how it relates to user interface design issues.

In many ways, our approach reflects the arguments that occurred in speech recognition research. For many years, automatic speech recognition systems were 'knowledge-based,' involving complicated pseudo-formal production rules. Not only did these systems have poor recognition performance, errors were difficult to analyse. In the early 1990s, though, hidden Markov models [30] were built of a variety of speech phenomena, from individual sounds through to intontation patterns [9]. These models were analysable (so that improvements could be made systematically), simple and formal and had the great advantage of working very effectively (achieveing some 96% recognition on continuous speech large vocabulary tasks).

A push-button device can be represented as a finite state machine, where each state is something distinctive the device is 'doing' (possibly including being off). Pressing buttons (or perhaps doing other things) on the device change its state or possibly leave it in the same state. For any particular state, each button always does the same thing. If somehow a button does different things in the same state, then we are mistaken in assuming it is the 'same' state. However, we can choose to call different things the device does the same state: for example, we might decide that for some purposes what time a clock shows does not matter — all times could then be classed as one state. For many tasks, whether a clock shows 17:28 or 17:29, say, is immaterial: for an analysis we may only be interested in whether the clock is running or not, or perhaps whether it is displaying a morning or afternoon time.

The states are numbered $1, 2, 3, \ldots N$. In principle we can do this for any sort of device, and when suitable design tools are used no manual work is involved in counting off the states. The *adjacency matrix* (also known as the state transition matrix) of the device is an $N \times N$ matrix A where each element A_{ij}:

$$A_{ij} = \begin{cases} 1 & \text{if there is a button that changes state } i \text{ to state } j \\ 0 & \text{otherwise} \end{cases}$$

As a concrete but simple example, consider a simple battery torch, with two buttons ON and OFF. There are numerous states: the torch may have no batteries, or it may have dead batteries, it may have one missing, it may have a dud light bulb, it may be on, and so on. Clearly, some of the states we can imagine will not be sufficiently interesting to be considered distinct. The following table is

a preliminary definition of a simple torch, where the number of states has been tentatively fixed at 3.

State	Press ON	Press OFF	Remove battery	Add battery
1: Switched on, with battery	1	2	3	1
2: Switched off, with battery	1	2	3	2
3: No battery	3	3	3	?

There are some interesting problems visible already. For example, how can you add a battery to a torch that already has a battery? Should we add more states to cater for "squashed battery," "broken torch," or "frustrated user"? Once the table starts to get realistic and represents more and more of the world, it may be hard to know where to stop. For the time being, we will only be interested in successful operations (i.e., only inserting a battery when that is possible). There is another problem, indicated by the question mark in the table. If a battery is inserted when in state 3, the bulb will either come on or stay off. Which? This is the situation alluded to above: state 3 is in fact two states: no battery and off; no battery and on. For many design purposes, having a consistent model is more important than having a complete one — not that it is feasible to have a complete model of a human-machine system. Here is a refined version:

State	Press ON	Press OFF	Remove battery	Add battery
1: On, with battery	1	2	3	1
2: Off, with battery	1	2	4	2
3: No battery (on)	3	4	3	1
4: No battery (off)	3	4	4	2

This can be represented as a 4×4 adjacency matrix:

$$A = \begin{pmatrix} 1 & 1 & 1 & 0 \\ 1 & 1 & 0 & 1 \\ 1 & 0 & 1 & 1 \\ 0 & 1 & 1 & 1 \end{pmatrix}$$

The matrix is read as follows: each row is a state-from, and each column is a state-to. Thus row one indicates there are possible transitions from state 1 to states 1, 2, and 3, but not to state 4.

Notice the abstraction of the user interface as represented by the matrix: the matrix certainly does not tell us everything about the design. Nevertheless, the matrix has an interesting structure, even though one cannot tell from the matrix what any of the operations are; in fact, the matrix does not show what the names of the states are either.

3.1 Concrete issues of scalability

A simple digital alarm clock has states for 24 hours and 60 minutes for the time of day and for the time of the alarm, and all times two for the possibility that the alarm is either enabled or disabled: that is $24 \times 60 \times 24 \times 60 \times 2 = 4147200$ states in all. If this FSM was represented as a simple adjacency matrix (as we can do explicitly for the torch) it would have over four million rows and columns, and without compression it would require about 2000 gigabytes of computer memory! However we argue that 'large' matrices are not a practical problem.

For a device with b buttons, no row in the matrix has more than b non-zero entries. For example, if we replace the two torch buttons (ON and OFF) with a single push-on/push-off button, its matrix would have one fewer non-zero entries per row:

$$A' = \begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix}$$

From this new matrix, incidentally, it is clear that *any* action the user does always changes the state: the leading diagonal of the matrix is all zeroes. Pressing the push-on/push-off button always changes the state, and (as before) successfully removing or adding a battery also changes the state.

Indeed the number of buttons is usually kept relatively low. Even a general purpose computer only needs about 50 keys (a QWERTY keyboard) to operate. Thus the matrix is sparse (mostly zero), and as the number of states increases the the matrix becomes exceedingly sparse. Furthermore, buttons usually do something reasonably consistent (e.g., the off button always makes the same state transition). Typically, then, a large adjacency matrix can be easily treated as a set of rules rather than as an explicit matrix with every element taking up memory, so it can be quite compact — in fact, if there is *no* way to represent the matrix compactly, there is no way to make the device easy to understand for a user, and certainly no way to program it systematically. See reference [3] for discussion of 'matrix free' methods, which provide the analytic power without the cost of large, explicit matrices.

3.2 Introducing empirical data

We have seen how an adjacency matrix can represent (an abstraction of) a finite state machine, but it 'knows' nothing about the user. But we might know, for instance, that users are more likely to add batteries to a torch when there are no batteries in it than when the bulb is on. The adjacency matrix tells us that a user can remove batteries from a torch that is on — it does not say whether this is likely to happen. As a next stage in realism, we introduce the probabilities of the user making the device change state. We refine the adjacency matrix to the *transition probability matrix*, P.

Continuing with the torch example, below we give some example values for P.

$$P = \begin{pmatrix} 0 & 0{\cdot}9 & 0{\cdot}1 & 0 \\ 0{\cdot}8 & 0 & 0 & 0{\cdot}2 \\ 1 & 0 & 0 & 0 \\ 0 & 0{\cdot}1 & 0{\cdot}9 & 0 \end{pmatrix}$$

The user may not do some things for very long times, if ever, but so far as the outcomes represented in the matrix are concerned there are no other possibilities than to enter one of the four states. Necessarily, each row in the transition matrix sums to one: the user does *something* with probability one.

The probabilities here (which we have made up) would show that a user is more likely to switch a torch off than to remove its batteries. If the torch is on, with probability 0·9 the next change of state will be the torch being off, and with probability 0·1 the user might remove the battery. Or if the torch is off with no battery in it, with probability 0·9 the user will try to switch it on (though, of course, the torch will not light). We could make the probabilities more realistic, for instance by collecting data on actual users' behaviour — however, we are using the example to explain the method, not to analyse torches or their use in depth.

Clearly, when A_{ij} is zero, P_{ij} is zero, because knowing something about the user's probable behaviour cannot make the device do things it cannot do. But the probabilities add more information.

At this stage it may appear that there is no obvious advantage in using a matrix to represent the probabilities: it looks like maths for its own sake. This is not the case; in fact, matrix algebra is very useful.

Consider that a user may pick up a new torch in state 4 (no battery and off). What will happen next? By inspection of the matrix, we can see the torch will go to state 2 with probability 0·1 and state 3 with probability 0·9. In general, at any time the torch has various probabilities for being in each possible state; we can represent these probabilities in a *state probability vector*, v. When a new torch is picked up, off with no batteries in it, the probabilities are $v_0 = (0 \;\; 0 \;\; 0 \;\; 1)$ and after an operation they are $v_1 = (0 \;\; 0{\cdot}1 \;\; 0{\cdot}9 \;\; 0)$ — these figures are determined by the probabilities in the matrix we have already established. In matrix algebra we have simply $v_1 = v_0 \times P$, that is,

$$(0 \;\; 0{\cdot}1 \;\; 0{\cdot}9 \;\; 0) = (0 \;\; 0 \;\; 0 \;\; 1) \times \begin{pmatrix} 0 & 0{\cdot}9 & 0{\cdot}1 & 0 \\ 0{\cdot}8 & 0 & 0 & 0{\cdot}2 \\ 1 & 0 & 0 & 0 \\ 0 & 0{\cdot}1 & 0{\cdot}9 & 0 \end{pmatrix}$$

In general, we can find the probabilities for any time in the future:

$$v_2 = v_1 \times P = v_0 \times P \times P$$

$$v_3 = v_2 \times P = v_0 \times P \times P \times P$$

and so on. In general, since repeated multiplication is the same as raising to a power:

$$v_n = v_0 \times P^n$$

If we assume that P does not change, then this is a so-called homogeneous Markov chain. Many mathematical results are known for Markov chains.

3.3 Usability

To assess the usability of a device, amongst other factors, we want to know how hard (in some sense) the device is to use. The number of state transitions a user takes to achieve some task is an obvious and simple measure of difficulty. If the number is huge, possibly the user will not live long enough, and the device will be impossible to use; or if the number is zero, the device is telepathic and (unbelievably) easy to use! For intermediate numbers, the more transitions required make the device harder to use. Transitions may take different amounts of time; for a device like the torch, inserting a battery takes longer than pushing a button.

Unlike many classic usability analyses, because we are using probabilities, we are not restricted to considering only 'error free' behaviour on the user's part. In particular, the sentiment that a user taking a long time has more time to make errors and so takes even longer, is already built into the approach; in fact, as our examples below show, the damaging effects of errors on user performance are starkly revealed. Section 3.5, below, discusses one way of introducing knowledge of correct operation, and we shall see that our approach gives a very good way of visualising the impact of knowledge on usability.

Given the transition probability matrix P of some device, we want to be able to answer questions like: "If a user starts in state i, how hard is it to get to state j?"

Because P is a transition probability matrix, the "how hard?" question translates more precisely to "what is the mean number of transitions to first reach state j starting from i?" This is easily answered by a Markov chain model. Appendix B derives a formula for obtaining this number from any matrix P. The next section discusses what we can do with the number. (Many other measures can be obtained from a Markov model, but one example will do for the purposes of this paper.)

In practice, P can have probabilities chosen to suit the known characteristics of the user interface, or of a user's behaviour (for certain tasks, or averaged over a suite of tasks). We can most easily assume all button presses are equiprobable (as we do in all subsequent examples below) — this represents the "walk up and use" case well for some devices. Our analysis is here restricted to homogeneous Markov processes, meaning that the probabilities are not conditional (e.g., on the user's prior actions or what they learn); but the probabilities can be different for different states or buttons — say, if some are physically larger, or lit up in certain states. Setting the probabilities to reflect this is straight forward (e.g., see §4.4).

In real-user based usability simulations, designers are able to trace button press events — and hence calculate average goal completion efforts and times, so once a prototype device has been built and can be used, transisition probabilities can be acquired from actual user behaviour. A Markov model provides a good way of recording the behaviour. Section 4.1 shows that simulation and analysis are easily combined: the analytic approach can easily be simulated, the simulation data can easily be combined with further analysis, and so on. Moreover a random approach (e.g., simulating a random user) has been shown to be very good at identifying programming problems [11], and therefore would be of use when the user interface was not automatically derived from the specification.

3.4 Knowledge as a function of cost

The so-called "cost-of knowledge characteristic function" has been used to represent the cost of acquiring knowledge about a device [1]. If we represent cost by number of buttons pressed (which is straight forwardly related to time), and knowledge by the number of states visited by the user, then the cost-of-knowledge graph plots the maximum number of states that can be visited by at most a given cost. The graph can be plotted from empirical data, by assuming the user knows exactly how to use the device, or — more realistically, allowing for errors — taking the cost from a Markov model.

Although such graphs are useful in design (e.g., to guide reduction of average costs of tasks) they might better be called cost-of-access graphs, since they measure state accessibility. It is unlikely that a user's knowledge about a device increases linearly with merely accessing states. Moreover, knowledge of states (what a device does) is not knowledge of use (how to get it to do those things).

3.5 Usability as a function of knowledge

To get more realistic usability metrics we need to consider the user's knowledge of how to use a device. Our approach is to take a mixture of a 'perfect' error-free approach of performing a task with the original 'ignorant' P. We define the user's 'knowledge factor' k as a number $[0\,..\,1]$, essentially a probability they will behave like a fully-knowledgeable designer rather than randomly. If $k = 1$, the user's knowledge is equal to a designer's, and they can do anything optimally; if $k = 0$ the user has no knowledge, and they act randomly with no preferences.

The perfect approach is what a designer knows is the best way of performing a task. This is easy to determine from P, by taking the shortest allowable sequence of transitions, and setting those transitions with a probability of one. (Shortest path algorithms are well known; *Mathematica* provides one that can be used directly on a transition matrix.)

The transition probability matrix for a user with knowledge k is then $kD + (1 - k)P$, where D is the 'perfect knowledge' (designer's) transition probability matrix (with 1s on the optimal transitions) and P the original 'knowledge-free' matrix. As we have defined it here, the knowledge k measures the knowledge to achieve a certain task optimally; modelling general knowledge of a device would require a set of matrices, D_g, one for each goal.

We can now easily work out the usability of a device in terms of the user's presumed knowledge. We can plot graphs of expected task completion cost against k. We can also view k as representing the user's accuracy: if we assume the user does know exactly what to do, then the lower k, the more errors they are making — until at $k = 0$ they are making so many errors that they are behaving randomly.

Although our approach in this paper uses Markov models, this is not essential for viewing usability as a function of knowledge. We could use cognitive models, or any other models that provide numbers. However, an advantage is that we can easily take combinations of models (in this case, linear combinations of D and P) without any artificial manipulations.

	States					
Buttons	Clock	QD	Timer1	Timer2	Power1	Power2
Clock	Clock	Clock	Clock	Clock	Clock	Clock
QD	QD	QD	QD	QD	QD	QD
Time	Timer1	Timer1	Timer2	Timer1	Timer2	Timer1
Clear	Clear	Clear	Clear	Clear	Clear	Clear
Power	Clear	QD	Power1	Power2	Power1	Power2

QD = Quick Defrost

Fig. 1. Specification of Jonathan Sharp's microwave cooker. Columns are states the device is in; rows are buttons. By knowing the current state and a button, the table gives the next state. Thus, pressing the `QuickDefrost` button (i.e., row 2 of the matrix) when in state `Clock` causes the device to enter state `QuickDefrost`. As in Sharp's original specification, notice that `Clear` is both a state name and a button name.

4. WORKED EXAMPLES

If we re-analysed a system that we knew had a usability problem, methodologically we could be criticised that we knew what sort of problems we were looking for. That would leave open whether such an approach was useful in the design process *before* problems are recognised. Instead, for our first example we take a specification directly from Sharp's PhD thesis [16] in interaction design. Sharp's thesis was concerned with the reliability of on-screen simulations for usability studies (he was more concerned with photo-realistic 3D models, rather than outline 2D models such as our simulation), and was not concerned with the usability of devices *per se*.

After analysing variations on the Sharp design (§4.3), subsequent examples are a mobile phone (§4.4), the *Genius* digital clock (§4.5), and a combination lock (a device intended to be hard to use) (§4.6).

4.1 A microwave cooker and its implementation in *Mathematica*

Sharp's rules for his microwave cooker are shown in Figure 1. From this, some simple manipulation in *Mathematica* gives us a finite state machine representation sufficient to perform analysis (complete details are given in Appendix A).

Mathematica Version 3 [29] has a simple and convenient scheme whereby buttons can be bound to arbitrary actions. This is a standard technique to implement 'easy to use' *Mathematica* packages: we simply exploit it to provide the user interface for the required device.[3] The *Mathematica* simulation of this microwave cooker is shown in Figure 2. With the simulation, we can also perform conventional usability studies, and obtain empirical data that could refine the probabilities used in the mathematical analysis.

The adjacency matrix for Sharp's microwave cooker is:

[3]The user interface code is not given here; but see [26], which provides complete code, compatibly with this paper's Appendix A.

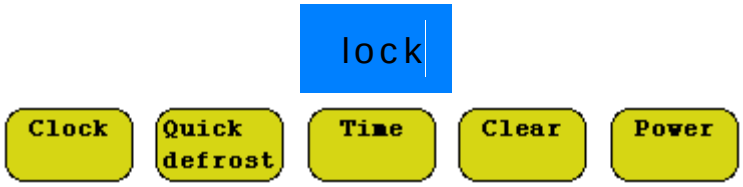

Fig. 2. Screen shot of a *Mathematica* user interface simulation, showing screen display and button arrangement. The device is currently in the clock state. The buttons can be derived directly from the button specification (though we have added a new line in one of the button names for clearer presentation). Clicking on a button calls the *Mathematica* function `press[`*name*`]`, which changes the device state and causes the display to change appropriately. Full code for this simulation is provided in Appendix A.

$$A = \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 1 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 1 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 \end{pmatrix}$$

We can now obtain (one line later in *Mathematica*) the all-pairs shortest paths (the quickest ways to get from any state to any other state):

$$\begin{pmatrix} 0 & 1 & 1 & 2 & 2 & 3 \\ 1 & 0 & 1 & 2 & 2 & 3 \\ 1 & 1 & 0 & 1 & 1 & 2 \\ 1 & 1 & 1 & 0 & 2 & 1 \\ 1 & 1 & 2 & 1 & 0 & 2 \\ 1 & 1 & 1 & 2 & 2 & 0 \end{pmatrix}$$

For example, to get from either state 1 (clock) or state 2 (quick defrost) to state 6 (power 2) takes three button presses. The leading diagonal is all zeros because it takes no steps to get from a state to itself.

The entries in this matrix are the button-pressing costs for an error-free user, who knows what they are doing. Such an error-free user must be able to identify each state correctly (or at least be able to correctly identify the starting state for any task, and then know what to do from memory).

Evidently, for this device a user can get from any state to any state in at most three button presses: the device looks easy to use. The shortest paths are routes that are obvious to designers, especially if they use tools to visualise the state diagram (see Figure 3, which, though tidied up for typesetting this paper, is in the form drawn by *Mathematica*). Note that it would be easy to demonstrate such a device and give a persuasive impression that it was easy to use [24]. However the shortest path numbers are much smaller than a Markov model predicts — e.g., for this device getting from, say, `power1` to `power2` takes 120 steps. This is so large it deserves explanation:

—A Markov model doesn't 'realise' when it is going around in circles, so it gets

stuck in repetitive behaviour easily. (In other words, a homogeneous Markov model does not learn.)

—The button-pressing probabilities used in the example are all equal, regardless of state. A more accurate model would use more realistic probabilities (e.g., as measured from real users' behaviour).

—Designers tend to seriously over-rate the ease of use of their system, even for something as clear-cut as Sharp's microwave cooker.

Humans can also 'loop' when they do not fully understand a device. An all-too-familiar anecdote will suffice to illustrate the problem. Recently, one of the authors and his 17 year old son were trying to program their Goodmans VN6000 video recorder following a power cut, which had reset the date and time.

The task, therefore, was to reset the clock to the current time, then use the VideoPlus+™ system for entering the code for the programme they wanted to record.[4] Setting the clock was easy: the remote control has a menu button, and all subsequent interaction was through a TV on-screen dialogue. Then the VideoPlus+ code had to be entered. However the on-screen menu only had "`VIDEOPlus+ PRESET`" as a choice, which was explored. This seemed to allocate VideoPlus+ codes to TV channels, and was apparently correctly set despite the power cut. There was a menu choice for "`CHANNEL PRESET`," and this set UHF channels to TV channels, and this too was correctly set. Perhaps the VideoPlus+ system only worked when it 'knew' the clock was running? Having successfully set the clock, the users therefore switched the recorder on and off, and tried again.

Despite the 'user team' including a teenager (teenagers are supposed to understand these things), both users 'looped' for about 40 minutes before despairing and hunting down the video recorder manual.

The correct (that is, the manufacturer's idea of 'correct') operation was to press another button on the remote control labelled "`VIDEO Plus+`"! They had not spotted it because they had become drawn into the many on-screen choices offered by the menu system.

A Markov model of this interaction would also have taken a long time to solve the problem, because it would have spent a similarly proportionate time in the menu system. A designer should therefore consider the large numbers Markov models typically generate as significant clues to improving designs.

4.2 Knowledge/usability graph for the microwave cooker

We take the task to get from `clock` to `power2` state in Sharp's microwave cooker and examine the knowledge/usability graph. Recall that the graph shows the expected time given a transition probability matrix $kD + (1 - k)P$, where D is a 'perfect knowledge' (designer's) matrix (with 1s on the optimal transitions) and P the

[4]VideoPlus+ uses a number (typically printed along with the TV programme listings) to specify the channel, date, and start and end times of a broadcast programme. Given how hard most video recorders are to program, entering a single, humanly meaningless, number of many digits is easier than working out how to enter the different parts of the timing information separately. The VideoPlus+ code is a hash code of the information, and is designed so that more common timings have shorter codes. For example, 258 is the code for channel 1, 18:00–18:30 on 19 April, but 46140247 is the code for channel 5 at 00:45–03:45.

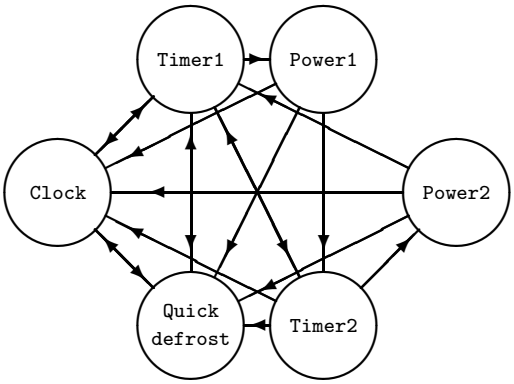

Fig. 3. Sharp's microwave cooker, drawn as a directed graph. This is a ranked embedding: states drawn in the same column take the same number of button presses from (in this case) the `clock` state. (So `power1` takes 2 steps to reach from `clock`, as does `timer2`, and `power2` takes 3 steps.)

original 'knowledge-free' matrix. The values of P (random use) and D (perfect, or designer's, use) used are shown below, and the resulting graph is shown in Figure 4 (solid line).

The probabilities in P are calculated assuming button presses are equiprobable: for this device there are 5 buttons, each pressed with probability $1/5$. Some buttons will leave the state unchanged, so the leading diagonal of the matrix has some elements greater than $1/5$.

$$D = \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} \quad P = \begin{pmatrix} 3/5 & 1/5 & 1/5 & 0 & 0 & 0 \\ 2/5 & 2/5 & 1/5 & 0 & 0 & 0 \\ 2/5 & 1/5 & 0 & 1/5 & 1/5 & 0 \\ 2/5 & 1/5 & 1/5 & 0 & 0 & 1/5 \\ 2/5 & 1/5 & 0 & 1/5 & 1/5 & 0 \\ 2/5 & 1/5 & 1/5 & 0 & 0 & 1/5 \end{pmatrix}$$

It is important to recall that these matrices are generated automatically (by simple work in *Mathematica*), and that changing the definition of the device would change the matrices. Again, the approach scales up to more complex devices than we can conveniently show in this paper (later sections discuss a larger device).

The downward slope of the graph is not surprising, but the shape of the curve is interesting. It can be seen that Sharp's microwave cooker is good in the sense that a little gain in knowledge initially gives a rapid improvement in task completion performance. Also, good, but imperfect knowledge, has comparable performance to perfect knowledge. In other words, most users get satisfactory performance with only a casual knowledge of perfect use.

4.3 Analysing variations of Sharp's microwave cooker

The 'random' user represented by P knows nothing about the device. How much would it help if, say, there were LEDs on each button, at least telling a user that these are the buttons that do *something*? So, whatever the user wants to do, this device ensures they do not need to waste time pressing useless buttons. Some devices, such as video recorders, which are often used in the dark, would certainly benefit in other ways as well — the user could easily locate functional buttons. Alternatively some mechanical arrangement might actually hide the non-functional buttons. A new matrix, P_{LED} can be defined to reflect random use of this modified design:

$$P_{\text{LED}} = \begin{pmatrix} 0 & 1/2 & 1/2 & 0 & 0 & 0 \\ 2/3 & 0 & 1/3 & 0 & 0 & 0 \\ 2/5 & 1/5 & 0 & 1/5 & 1/5 & 0 \\ 2/5 & 1/5 & 1/5 & 0 & 0 & 1/5 \\ 1/2 & 1/4 & 0 & 1/4 & 0 & 0 \\ 1/2 & 1/4 & 1/4 & 0 & 0 & 0 \end{pmatrix}$$

Although Sharp's microwave cooker has some explicit self-transitions, the diagonal of P_{LED} is entirely zero: the LEDs only light when a button changes the device's state.

A plot of this shows that the modified device (Figure 4, dashed line), is an improvement over the original. This isn't bad for a device that doesn't know what its user is trying to do! Interestingly, it does not give such a fast rate of improvement as the user learns how the device works. For more complex devices we would expect even better improvements if LEDs were used — and, we'd certainly expect the little LEDs to help sell the device in a shop! However, this simple analysis demonstrates the ease with which we can analyse and compare variations on a design.

Now consider modifying the device so that, rather than lighting LEDs on buttons that work, buttons *always work*. We can arrange that buttons not defined by Sharp return the device to `clock`. A designer might decide that this is a good idea because any 'incorrect' operation of the device would return it to a safe, well-defined state.

$$P_{\text{Always}} = \begin{pmatrix} 3/5 & 1/5 & 1/5 & 0 & 0 & 0 \\ 4/5 & 0 & 1/5 & 0 & 0 & 0 \\ 2/5 & 1/5 & 0 & 1/5 & 1/5 & 0 \\ 2/5 & 1/5 & 1/5 & 0 & 0 & 1/5 \\ 3/5 & 1/5 & 0 & 1/5 & 0 & 0 \\ 3/5 & 1/5 & 1/5 & 0 & 0 & 0 \end{pmatrix}$$

Modified in this way, Sharp's microwave cooker takes 129·167 steps to get from `clock` to `power2`, when $k = 0$. This is only a bit worse (3%) than the original version, but 67% worse than the LED version. (As before, since it is the same underlying FSM, it must take 3 when $k = 1$.) This alternative design should not be preferred over the LED idea, but whether it is an improvement over the original probably should not be answered just by considering Markov models — there may be psychological reasons to prefer or reject it.

Of course with other devices, the comparisons would come out differently: we are not concluding that LEDs *always* improve devices significantly, or that the

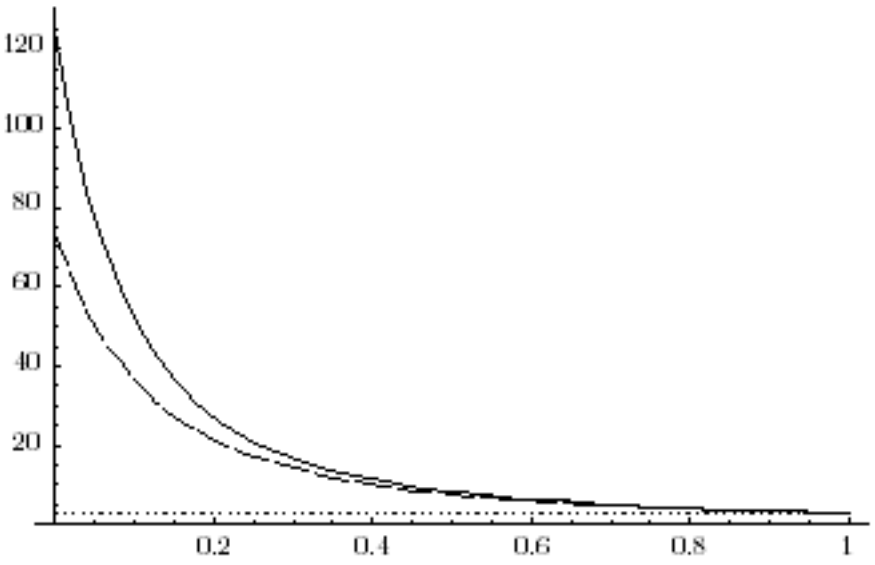

Fig. 4. Plot of expected number of steps against knowledge of device. The task is to get from `clock` to `power2` state. The solid line is the original microwave cooker, and the dashed line is the LED-enhanced device. The horizontal dotted reference line (expectation = 3) is the optimal task completion cost, that is, assuming the user knows exactly how to do it and makes no mistakes.

"no incorrect operation" style always makes a small improvement. What we have shown, though, is that making such comparisons is very easy.

The JVC UX-T20B stereo system is a simple commercial example of using LEDs in this way. Its "Compu Play" feature means that when in standby, only one button press is needed to start the system playing either tuner, CD, tape (or auxilliary input) depending on which button is pressed. (The power switch, then, is only needed when the user is not going to play something immediately but instead, for example, set the alarm.) Its "Illumi Magic" feature is linked to an infra-red sensor, so when an object approaches the sensor, the buttons that activate the Compu Play feature are highlighted with a LED strip near the appropriate buttons. Thus, by vaguely waving a hand at it, it is enough to light the LEDs and from that, very easy to start the machine playing in whatever mode is required, even when the machine is close to the floor in a dark corner of a room.

Markov models expose the problem of 'looping' — of a user going around in circles and not making progress towards their goal. The LED-based device was easier to use because a large number of short loops were eliminated from the user interface. At the other extreme, the entire device could be a single loop, of maximal length. It would then be a *ring*. Rather than use push buttons, a ring has better affordance implemented using a rotary knob.

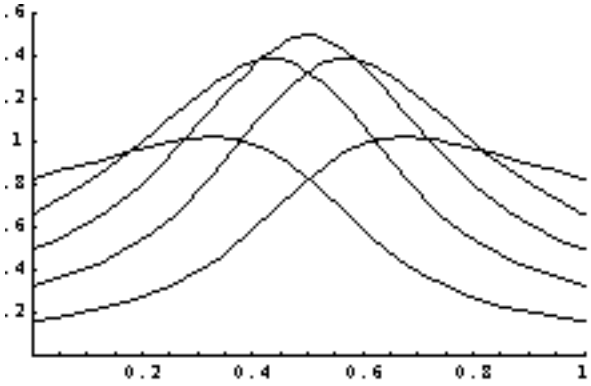

Fig. 5. Expected cost of using a knob to achieve the five states of Sharp's microwave cooker, starting from any given state, plotted against probability of rotating the knob in a specific direction. The cost (vertical axis) is measured in total revolutions, assuming the six knob positions are equally distributed around a circle — multiplying the scale by 6 makes it the number of 'clicks.'

Suppose a knob is used as the user interface to Sharp's microwave, and that (due to its design features) it is turned clockwise with probability p and anti-clockwise with probability $1-p$. The transition matrix is:

$$P_{\text{Ring}} = \begin{pmatrix} 0 & p & 0 & 0 & 0 & 1-p \\ 1-p & 0 & p & 0 & 0 & 0 \\ 0 & 1-p & 0 & p & 0 & 0 \\ 0 & 0 & 1-p & 0 & p & 0 \\ 0 & 0 & 0 & 1-p & 0 & p \\ p & 0 & 0 & 0 & 1-p & 0 \end{pmatrix}$$

The rather attractive Figure 5 shows the expected cost of reaching, from any state, each of the device's five others. Interestingly, the worst average cost (over all *six* possible goals) arises when $p = 0{\cdot}5$, which corresponds to an unbiased knob. From a purely Markovian analysis, a one-way knob would be more efficient to use ($p = 0$ or $p = 1$). Clearly, though, a user's actual performance would be more sophisticated, and a one-way knob would be sub-optimal. Nevertheless, the costs are so much lower than for a push button user interface that there could be merit in considering this style of interface further — particularly for 'walk up and use' interfaces.

A ring has only one loop, but some states are far away. Another radical alternative is a *star*. A star has one state in the middle, and the others radiating off it. Each of the 5 non-central states have a single transition, back to the centre. Thus, this design requires six buttons: five to get from the centre to each of the other states, and one to return from them to the centre state. Designed like this, the average cost to reach any state from the centre is 9, and from any non-central state, 10. This is a bit worse than the ring, but better than the original design —

at least, so far as the numbers are concerned!

A star suffers from having labelled buttons that only work some of the time. The 'return to centre' button only does anything if the device is not already at the centre state; and the other five buttons only work when the device is in the centre state. Worse, these five buttons do not always *leave* the device in the appropriate state when they are pressed.

If six buttons are going to be used, as there are six states, then the complete symmetric digraph (K_6^*) is a natural design choice: there is a transition from every state to every other state. The transition probability matrix is trivial: every element is equal to $^1/_6$. The average cost to reach any state is now 6, or to be precise — if a user walks up to the device, not knowing what state it is in, or if they don't bother to check and *always* press at least one button — the average cost is 5·2 presses — and that is if $k = 0$. When $k = 1$ (i.e., the user knows what they are doing), the K_6^* design takes 0·8 presses on average (1 press in the worst case), which is much faster than Sharp's original, which takes 1·2 presses on average (3 presses in the worst case). That seems like a useful gain at the cost of only one button; and it is not just a numerical gain, since the buttons *always* leave the device in the appropriate state — this design is both faster and it is mode-free.

4.4 A larger device: the Nokia 2110 mobile phone

Sharp's microwave cooker has only six states, and the analysis is not intrinsically difficult. We now examine the function menu of a Nokia 2110 mobile phone. This part of the phone has 89 states.

The function menu of the Nokia 2110 is controlled by four buttons, two 'scroll' buttons that move up and down in a menu, and two selection buttons that have changeable ('soft') meanings as shown in the phone's display panel. Initially, these two buttons show `menu` and `memory`. The user would press `menu` (which then disappears), and the other button becomes `quit`. When the user scrolls up or down the menu, the first button becomes `select`, which either selects the function shown in the menu, or selects a further sub-menu. The `quit` button quits each level of the sub-menus, taking the user back to the position where that menu was selected. The scroll buttons can be pressed repeatedly, and cycle through any given level of the menu hierarchy. There are a few other features, such as being able to press numeric keys to select functions faster than searching for them step-by-step in the hierarchy.

For reasons of space we do not show the data here. Using a basic probability matrix of equiprobable button presses, we find the cost to be 687,415 (for the random user) for the task of setting selecting "incoming calls" (a selection in the "call barring" menu, itself a selection in the "security options" menu), starting from standby. This number is so large because of the effect of the `quit` button, which the knowledge-free model repeatedly uses, and therefore hinders its reaching any desired goal.

The knowledge/usability graph as used in the analysis of the Sharp microwave cooker combines the random transition matrix P with a matrix D representing perfect knowledge of how to use the device for the task in question. For the Nokia mobile phone, what would happen if D was instead a matrix representing a user who avoided using the `quit` button? In other words, the knowledge k is the knowledge

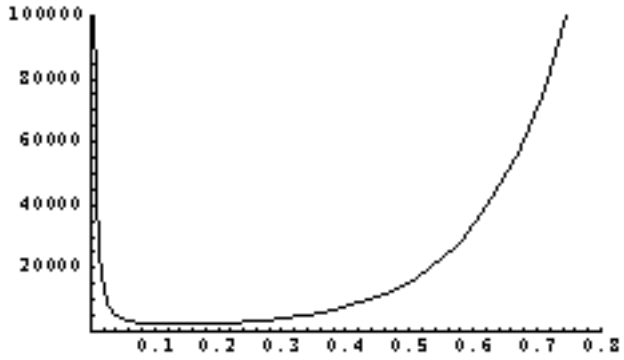

Fig. 6. Expected cost of using the Nokia 2110, depending on the relative use of the quit menu button. This is a knowledge/usability graph, where increasing knowledge (moving towards the right in the graph) is to increasingly avoid using the quit button. The graph shows clearly that there is an optimal use of the quit button: if used too much (at the left of the graph), the user gets slowed down going around in circles. If the user *never* uses quit (beyond the right of the graph), they would get stuck because they could never correct mistakes: the graph climbs off to an impossible device as k becomes closer to 1.

not to use the `quit` button. Figure 6 shows the resulting graph for the Nokia 2110.

At $k = 0$ (to the left of the graph), the user uses `quit` too much — and therefore often goes around in circles. (In the model shown here, $k = 0$ has the `quit` button used fairly: one quarter of the time on average.)

With $k > 0{\cdot}5$ the difficulty of using the phone increases dramatically. Here we are seeing that if the user makes a mistake (this is using a random model, so they *will* make a mistake), they will get stuck forever unless they use `quit` — without `quit` there is no way out of a wrongly-selected menu, except by selecting one of the functions the user does not want!

There is an optimal use of the `quit` button, around $k = 0{\cdot}135$. As a hint to the designer of the mobile phone, this could be taken to mean make the `quit` button smaller, so the user can use it, but not as often as the other buttons. To do this on a device like the Nokia 2110, where the `quit` key is a multi-purpose key, could cause problems in other parts of the user interface. However the Nokia 2110 has a much smaller button `c`, normally used for correction (and for returning to standby when in the menu hierarchy). This button could have been used with the same meaning as, but replacing, the current `quit` key.

If the `quit` key is so critical, which it certainly is compared to the other menu-selection keys, then the user interface design that makes it so should be examined closely. It may be that the method of quitting submenus is the problem, not the frequency of use of the `quit` key itself.

In many ways the problem with this sort of analysis — and certainly for picking examples to illustrate its use in a paper such as this — is the whole range of new

```
startState = s[stable, 0, 0, 0, 0];
clock[s[stable, a_, b_, c_, d_]] =
             s[flashing, a, b, c, d];
clock[s[flashing, a_, b_, c_, d_]] :=
             s[running, a, b, c, d]
                                  /; a+b > 0 && 10a+b < 13 && 10c+d < 60;
reset[s[flashing, _, _, _, _]] =
             s[flashing, 0, 0, 0, 0];
hour10[s[flashing, a_, b_, c_, d_]] =
             s[flashing, Mod[a+1, 10], b, c, d];
hour1[s[flashing, a_, b_, c_, d_]] =
             s[flashing, a, Mod[b+1, 10], c, d];
minute10[s[flashing, a_, b_, c_, d_]] =
             s[flashing, a, b, Mod[c+1, 10], d];
minute1[s[flashing, a_, b_, c_, d_]] =
             s[flashing, a, b, c, Mod[d+1, 10]];
```

Fig. 7. The *Genius* clock in *Mathematica*. A state is represented as `s[`*mode*`,` *tens-of-hours digit*`,` *units-hours digit*`,` *tens-of-minutes digit*`,` *units-minutes digit*`]`. The clock starts in `startState`. The rules specify the behaviour of buttons, by defining their functions on the state. Rules to stop the clock running are not shown.

questions that are immediately suggested!

Given that *Mathematica* had been set up for the analysis, the only hard work in analysing the Nokia phone was working out the transition matrix. This was very tedious — of course, if a device manufacturer collaborated with us, or if the analysis was performed by the manufacturer, the device specification should be known explicitly. Finding the transition matrix would then be completely trivial.

4.5 The *Genius* microwave cooker

The *Genius* is a Panasonic microwave cooker. The digital clock can display any decimal number 00:00 to 99:99, though it can only run when it is showing a 12 hour time (between 01:00 and 12:59). There are six buttons that control the clock. There are four buttons, one below each digit, which are used to increment the corresponding digit. One button, `reset`, resets the clock to its initial switch-on state. One button, `clock`, makes the clock run if it is showing a valid twelve hour time. The clock can be in several modes (class of state): it can have its colon flashing or stable, and the clock may or may not be running.

Although we have included the transition to switch the clock on (e.g., as occurs when the microwave cooker is plugged in to an electricity supply), we shall ignore transitions like switching it off (presumably, unless the user gets cross with the clock, they will not switch it off)! The *Mathematica* specification of this simplified *Genius* is shown in full in Figure 7.

The clock (as specified) has 30,000 states, but it is easier to visualise it as a four state device: (1) a start state, 'switched-off' — from which the only transition is to press the `clock` button to switch the display on to show 00:00, an invalid time; (2) a state where the clock shows a valid time but is not running; (3) a state where the clock shows an invalid time; and (4) a state where the clock shows a valid time and is running. A run through the 64,322 possible state transitions provides the

following transition probability matrix:

$$P = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & {}^{17}\!/_{36} & {}^{13}\!/_{36} & {}^{1}\!/_{6} \\ 0 & {}^{7}\!/_{464} & {}^{457}\!/_{464} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

We have thereby reduced a huge matrix to a 4×4 matrix, and the sums will be much more manageable. Appendix C proves the validity of this approach.

The expected number of state transitions to get from switch-on to the clock running is 216·905.[5] If we make the obvious modification and remove state 3, so the clock can only show valid times (we also have to modify the initial state so that at switch-on the clock shows a valid time, such as 12:00), then the figure becomes 7 — a big improvement.

Interestingly, our experiments ([21]) with people showed that the Markov model does better than humans: some humans cannot set the clock at all, because they think it is a 24 hour clock (if they are tested in the afternoon, they can easily set the *Genius* to a time after 12:59, but the clock won't run). This is an example of where knowledge makes using a device harder; conversely, it is an example where the designers' tacit knowledge ("nobody uses 24 hour clocks") was accidentally built into a device. If you think you know how something works, but you are wrong, you may be permanently stuck; the Markov analysis suggests that under such circumstances (should you notice them) you should press buttons at random. This would then give an example of how to set some time, and having discovered that, it should be easier to set the required time.[6]

We could argue that the reason why children can use devices more easily than adults is because they do not have adult preconceptions about how devices should work; they are more like ignorant Markov models! Or, to put it another way, the reason why adults find gadgets awkward is that they are not designed properly.

4.6 Combination locks

Most devices are supposed to be easy to use, and therefore should have low transition costs. In contrast, some devices are intended to be hard to use. We now consider a simple security lock.

Consider a dial security lock, where the user can spin a dial, and they are supposed to select the right number. If we simplify the device to a two state machine and a dial with a chance of p of being set correctly (e.g., with ${}^{1}\!/_{p}$ choices, only one of which is correct), it has a probability matrix

$$P = \begin{pmatrix} 1-p & p \\ 0 & 1 \end{pmatrix}$$

If the user knows nothing, the mean time to 'cracking' the lock (using the formula from Appendix B) is ${}^{1}\!/_{p}$. In general, if the user knows k (defined as before), the mean time is $1/(k+p-kp)$. If p is large (i.e., the security lock is easy), then it doesn't

[5] As indicated in Appendix C, the number of button presses expected of the user will be higher than the number of state transitions.

[6] Not that microwave cookers need to know the *correct* time anyway!

really matter how much the user knows: the lock is easy to open even if the user doesn't know the right combination. If p is very small, then the usability/knowledge curve is a hyperbola, $1/k$, which means, roughly, the less you know the more a little knowledge helps.

5. FURTHER WORK

Markov modelling provides a robust and general purpose tool for user interface design and analysis. There are therefore many opportunities for further work. Here we list just three significant research areas that are opened up:

—Many definitions of usability are couched in terms such as "a percentage of users can complete a percentage of tasks in a given time." Such definitions, with the appropriate calibration, are answerable by using Markov models. The development of a suite of mathematical techniques to work with this conceptualisation of usability should be straight forward.

—In section 2 and in Appendix C we briefly discuss how to coalesce states in a FSM to provide alternative models of a system. Given that system designers and users typically have different models of a system, further work here would be very productive. For example, a system engineer never represents a large FSM of millions of states, but instead uses a programming language with conditionals, rules, functions. Different languages have different sorts features, and the resulting model the designer has will be determined by the language, not just their tacit conceptualisation. Can, then, user interface design languages guide designers into creating structures that are more easily modelled by users? For example Statecharts are one possibility: they are widely recognised as powerful design notations, and coincidentally they share some of the criteria discussed in the Appendix. Nevertheless we are unaware of any substantial work on whether 'neat' Statecharts would result in better user interfaces.

—Design tools could be constructed that provide analysis of user interface designs. All technical details of the analysis could be hidden, and designers could be presented with estimates of usability or task times. Such tools could also simulate the behaviour of systems with actual use, and could therefore calibrate their analyses. Developing such a tool, that is both powerful enough to be worth using in product design, and which is nonetheless easy enough to use by practitioners would be a significant project.

—Our knowledge/usability graph was based on a scalar parameter k that, ranging over 0 to 1, covers random to perfect knowledge of a device. We did not consider users who may have mistaken knowledge, and whose actions may be counterproductive rather than just inefficient. Since there are many ways to have incorrect knowledge, merely allowing k to be negative, say, is inadequate. A user may correctly know how to achieve the wrong goal, by confusion of function names. Generalising our approach to knowledge, to include conceptual errors, but not losing sight of the focus on usability and of obtaining design insights will be a difficult, and perhaps fruitful, line of research.

6. CONCLUSIONS

This paper suggests using a method with the advantages of mathematical clarity, ease of simulation, and which provides numerical measures that are ideal for comparing designs. We could have chosen more psychologically realistic methods than a Markov model, but we feel that the need for such methods must first be proved by showing more abstract approaches are inadequate. In fact, we *did* show that a Markov model rather obviously lacks realism, though this was not a disadvantage.

We will leave it as an open question whether and to what extent a mathematical model provides useful insights into good design in practice. We only assert it does: we have not done studies beyond the illustrative examples presented in this paper. We do not know how designers might be influenced. It may be that user interface development teams are not happy with mathematical approaches, and prefer (and are better skilled at) empirical methods. Further work could, in principle, embed mathematical analysis inside tools that designers are already familiar with ([23] gives an example).

This paper proposed an approach that is operational, and can be applied to abstract designs, prototypes and animations, or to fully working systems. It is scalable, and can accommodate complex systems, easily on the scale of typical interactive devices. It is applicable throughout the design cycle, at early design stages or late, indeed it can be used for conformance testing. Results are conservative and do not rely on psychological assumptions. Of course, it will be preferable to embed approaches such as ours transparently inside design tools to provide designs with the power of the method without the need for the craft knowledge.

Acknowledgements

The referees made substantial comments that have helped the presentation of this paper. The authors are indebted to Ian H. Witten (Waikato University) and Saul Greenberg (Calgary University) whose microwave cooker started it all. The present paper owes much to the collaborative work with Ian Witten described in [21], though the present paper corrects the mathematics. Richard Young and Ann Blandford provided invaluable and extensive criticism.

APPENDICES

A. COMPLETE *Mathematica* CODE

The *Mathematica* code shown in this Appendix is *complete working code* to simulate a user interface and to draw the figures and calculate the numbers quoted in the

body of the paper. For concreteness, this Appendix uses the definition of the microwave cooker from Figure 1. By editing the definition other devices can be simulated and analysed directly.

The code starts by loading the standard *Mathematica* package for combinatorics (to load a shortest path function, which we will need for calculating the designer's optimal transition matrix), and defines a utility routine.

```
<<DiscreteMath‘Combinatorica‘;
IndexOf[vector_, e_] := Position[vector, e][[1, 1]];
```

Here is Jonathan Sharp's definition of the device, written in *Mathematica* notation:

```
device =
{ { clock, clock, clock, clock, clock, clock },
  { quickDefrost, quickDefrost, quickDefrost,
    quickDefrost, quickDefrost, quickDefrost },
  { timer1, timer1, timer2, timer1, timer2, timer1 },
  { clock, clock, clock, clock, clock, clock },
  { clock, quickDefrost, power1, power2, power1, power2 }
};

buttonNames = { clock, quickDefrost, time, clear, power };
stateNames  = { clock, quickDefrost, timer1, timer2, power1, power2 };

numberOfStates = Length@stateNames;
numberOfButtons = Length@buttonNames;
```

Mathematica itself has powerful typographical features that could be used to present the definition of `device` as in Figure 1.

A.1 Example analysis and graph drawing

The first analysis discussed in the paper was for tasks getting from state `power1` to `power2`.

```
start = IndexOf[stateNames, power1];
goal  = IndexOf[stateNames, power2];
```

The random user matrix (called P in the paper) is directly calculated from `device`; button presses are treated as equiprobable, contributing `1/numberOfButtons`:

```
randomUser = Table[0, {numberOfStates}, {numberOfStates}];
Do[randomUser[[i, IndexOf[stateNames, device[[b, i]]]]]
             += 1/numberOfButtons,
   {b, numberOfButtons}, {i, numberOfStates}];
```

The designer's matrix (called D in the paper) is based on the optimal route from the start to the goal states. Notice how the random user matrix (which has non-zero elements precisely where there are transitions) is converted to a `Graph` type to find shortest paths. The definition of D depends on the choice of start and goal states.

```
designer = Table[0, {numberOfStates}, {numberOfStates}];
Do[Module[{p = ShortestPath[Graph[randomUser, {}], i, goal]},
          designer[[i, If[ Length[p] > 1, p[[2]], i]]] = 1],
   {i, numberOfStates}];
```

After defining the identity matrix of suitable dimensions and some utilities, we can give the definition of the mean first passage time in direct form (the formula used is derived in Appendix B):

```
Id = IdentityMatrix[numberOfStates];

One = Table[1, {numberOfStates}];

ZeroRowCol[matrix_, rc_] :=
  Table[If[ i == rc || j == rc, 0, matrix[[i, j]]],
   {i, Length@matrix}, {j, Length@matrix}]

meanFirstPassage[matrix_, start_, goal_] /; goal != start :=
  (Inverse[Id-ZeroRowCol[matrix, goal]] . One)[[start]];

meanFirstPassage[matrix_, start_, start_] := 0;
```

The expected time to get from the start state (`power1`) to the goal state (`power2`) is `meanFirstPassage[randomUser, start, goal]`, which equals 120. The knowledge/usability graph can be plotted by `Plot[meanFirstPassage[k designer + (1-k)randomUser, start, goal], {k, 0, 1}]` (see Figure 4).

A.2 Simulating the user interface

To simulate the device a global variable keeps track of the state of the device as buttons are pressed. We start the device in the initial state `clock`, by writing `state = clock`.

The following code constructs a row of buttons to control the device directly from the device specification, thus ensuring mathematical and empirical analysis are consistent.

```
CellPrint[Cell[BoxData[RowBox[
      Map[ButtonBox[ToString@#,ButtonFunction:>press[#],
```

```
                    ButtonEvaluator->Automatic]&,
          buttonNames]]],
      Active->True]]
```

The result is a row of working buttons (as in Figure 2). When a button is pressed, `press` is called as the action. A basic definition of `press` is given below, simply showing the name of the current state in the display, though it is possible to display any image if required.

```
press[theButton_] :=
  Module[{nb = ButtonNotebook[]},
    state = device[[IndexOf[buttonNames,theButton],
                    IndexOf[stateNames,state]]];
    NotebookFind[nb, "display", All, CellTags];
    SelectionMove[nb, All, CellContents];
    NotebookWrite[nb, Cell[ToString[state]]]
  ]
```

The device's simulated display is a cell with name `"display"` so `press` can locate it: `Cell["", CellTags -> "display"]`, which would be displayed as in Figure 2.

B. MARKOV MODELS AND EXPECTED FIRST ENTRY TIME

This appendix provides details of how a Markov chain can be used to model a user interface. Using this model, we extract the average times (numbers of steps, button presses, or state transitions) required to get from one state of the user interface to another.

Although many user-relevant measures can be obtained from Markov models, in the body of the paper we only used the mean first passage time M_{ij}, the expected number of state transitions to first reach a state j starting from state i. Specifically, for a transition probability matrix P, M is the corresponding matrix of mean first passage times:

$$M_{ij} = \begin{cases} 0 & \text{if } i = j \\ \left((\mathrm{I} - [j{\downarrow}P])^{-1} \cdot \mathbf{1}\right)_i & \text{if } i \neq j \end{cases}$$

where $[j{\downarrow}P]$ is the submatrix of P with row j and column j set to zero,[7] $\mathbf{1}$ is a vector of ones, and I the identity matrix. Writing the formula out in words:

—for $i = j$, the mean first passage time M_{ij} getting from some state to itself is zero;

—for $i \neq j$, given the matrix P, set row j and column j to zero, subtract from the identity matrix and find the inverse. The sum of row i of this inverse defines the value M_{ij}.

[7] $[j{\downarrow}P]$ is a transition matrix where state j is neither reachable nor has any action.

The mathematics may look complicated, but it provides a solid formal basis for the metrics used in this paper. Moreover the mathematics need only be done once to cover a very wide range of different systems: simply define the matrix P and initial and final states as appropriate. In practice, the analysis would be "inside" a user interface development tool and a designer need not be concerned with the formulae themselves. *Mathematica* can solve such equations either numerically (e.g., to plot graphs) or symbolically, for example using the code given in full in Appendix A. As an example, the matrix P_{Ring}, discussed in the body of the paper, gives an expected first entry time for one state of $\frac{5-16p+21p^2-12p^3+3p^4}{6(1-4p+7p^2-6p^3+3p^4)}$. The discussion of the combination lock (§4.6) made simple use of such symbolic solutions.

The rest of this appendix attends to the formal derivation of the formula.

The elements of probability theory required to describe this model may be found in [5]. For events A and B we use $\Pr(A)$ to denote the probability of A occurring, and $\Pr(A \mid B)$ to be the probability of A occurring given that B has occurred. For a random variable X, $\mathrm{E}(X)$ denotes the expectation or the mean value of X.

Assume the set of all possible states of a user interface is S and for simplicity assume that $S = \{1, 2, \ldots, |S|\}$. The Markov chain for the user interface is the sequence $\{ X_n \mid n = 0, 1, \ldots \}$ where each X_n is a random variable that takes values in S. Define, for all $i, j \in S$, the one-step transition probability to be $P_{ij} = \Pr(X_1 = j \mid X_0 = i)$. Indeed, as the user interface does not change with time, we have that

$$P_{ij} = \Pr(X_{n+1} = j \mid X_n = i) \text{ for all } i, j \in S, n = 0, 1, \ldots$$

As it is certain X_{n+1} has some value regardless of the value of X_n, we have:

$$\sum_{j \in S} P_{ij} = 1 \tag{1}$$

As in the paper, take $P = \{ P_{ij} \mid i, j \in S \}$ to be the matrix of all the one-step transition probabilities. In other words, equation (1) is the already familiar result that the rows of the probability transition matrix P sum to 1.

For each $j \in S$, define $N(j) \mid X_i = k$ to be the random variable being the number of steps to reach state j starting from $X_i = k$. Then take M_{ij} to be the mean number of steps to reach j given that the system started in state i. That is,

$$M_{ij} = \mathrm{E}(N(j) \mid X_0 = i)$$

Trivially $M_{ij} = 0$ for $i = j$; so from now on take $i \neq j$. Now, by standard results on conditional expectations,

$$M_{ij} = \sum_{k \in S} \Pr(X_1 = k \mid X_0 = i) \times \mathrm{E}(N(j) \mid X_1 = k)$$

that is, we have the equation

$$M_{ij} = \sum_{k \in S} P_{ik} \times \mathrm{E}(N(j) \mid X_1 = k) \tag{2}$$

Now if $X_1 = j$ then the process stops as the system has reached j. Thus, $N(j) = 1$ and $\mathrm{E}(N(j) \mid X_1 = j) = 1$. However, if X_1 is anything other than j, which we may write $X_1 = k$ for $k \in S \setminus \{j\}$, then the process continues as if it had started from k. Hence $\mathrm{E}(N(j) \mid X_1 = k) = \mathrm{E}(N(j) + 1 \mid X_0 = k)$. That is, for $k \neq j$

$$\begin{aligned} \mathrm{E}(N(j) \mid X_1 = k) &= \mathrm{E}(N(j) \mid X_0 = k) + 1 \\ &= M_{kj} + 1 \end{aligned}$$

Thus equation (2) becomes

$$\begin{aligned} M_{ij} &= P_{ij} + \sum_{k \in S \setminus \{j\}} P_{ik} \times (M_{kj} + 1) \\ &= \sum_{k \in S \setminus \{j\}} P_{ik} \times M_{kj} + \sum_{k \in S} P_{ik} \end{aligned}$$

which from equation (1) gives us that, for all $i, j \in S$ such that $i \neq j$:

$$M_{ij} = 1 + \sum_{k \in S} P_{ik} \times M_{kj}$$

This system of equations can be simplified. Let M_j be the column vector of the M_{ij} for which $i \neq j$. The equations are now given by:

THEOREM B.1. $M_j = \mathbf{1} + [j{\downarrow}P] \cdot M_j$

where $\mathbf{1}$ is the column vector of the appropriate size made up entirely of ones.

To use Theorem B.1 to find the average time to get from one state to another, we need to be sure that by solving the equation we actually have found the M_{ij}. Fortunately, we have

THEOREM B.2. *For each $j \in S$, $(\mathrm{I} - [j{\downarrow}P])^{-1}$ exists.*

It therefore follows that,

COROLLARY B.3. *The system of equations given in Theorem B.1 has a unique solution given by*

$$M_j = (\mathrm{I} - [j{\downarrow}P])^{-1} \cdot \mathbf{1}$$

Hence, as required

$$M_{ij} = ((\mathrm{I} - [j{\downarrow}P])^{-1} \cdot \mathbf{1})_i$$

The proof of Theorem B.2 is a consequence of the following two lemmas.

LEMMA B.4. *For each $k \in S$, $[k{\downarrow}P]^n \to \mathbf{0}$ as $n \to \infty$. That is, $[k{\downarrow}P]^n_{ij} \to 0$ as $n \to \infty$.*

LEMMA B.5. *If for some square matrix of real or complex numbers, A, $A^n \to \mathbf{0}$ as $n \to \infty$ then $(\mathrm{I} - A)^{-1}$ exists and*

$$(\mathrm{I} - A)^{-1} = \sum_{n=0}^{\infty} A^n$$

This last lemma is well-known (see [15]) so we omit the proof. However, an informal check will easily show that the definition given of $(\mathrm{I}-A)^{-1}$ satisfies, as it should,

$$(\mathrm{I}-A)\cdot(\mathrm{I}-A)^{-1} = \mathrm{I} = (\mathrm{I}-A)^{-1}\cdot(\mathrm{I}-A)$$

The proof of Lemma B.4 is provided for completeness as it is often given in much greater generality, and hence with complexity superfluous to our purposes (see [15]).

Proof of Lemma B.4 Fix some $k \in S$, and let $Q = [k\downarrow P]$. Because Q deals only with transitions omitting k, it represents the probability of getting from state i to state j in exactly one step without passing through state k. Also, Q^n is the probability of getting from state i to state j in exactly n steps without ever having passed through state k.

For a sensible user interface, it must be possible to get from any state $i \neq k$ to k after say some N steps (otherwise, the user interface has states which are not accessible!). But as Q^N represents the probability of not visiting k after N steps, it must be that

$$\sum_{j\in S\setminus\{k\}} Q^N_{ij} < 1$$

As in this sum, but for clarity we will implicitly take all further sums over $S\setminus\{k\}$. Now, by definition, for any n,

$$\sum_j Q^{(n+1)}_{ij} = \sum_j \sum_r Q^n_{ir} \times P_{rj}$$

which by equation (1) gives

$$\sum_j Q^{(n+1)}_{ij} \leq \sum_r Q^n_{ir}$$

Hence, for all $n \geq N$, if $\theta = \sum_j Q^N_{ij}$,

$$\sum_j Q^n_{ij} \leq \theta < 1$$

Moreover for each $m \geq 1$,

$$\begin{aligned}\sum_j Q^{N(m+1)}_{ij} &= \sum_j Q^N_{ij} \sum_r Q^{mN}_{ir} \\ &\leq \theta \sum_r Q^{mN}_{ir}\end{aligned}$$

Therefore, proceeding by induction, we have

$$\sum_j Q^{mN}_{ij} \leq \theta^m \tag{3}$$

But as $m \to \infty$, $\theta^m \to 0$. Thus the sums on the left-hand side of equation (3) tend to zero and form a convergent subsequence of the monotone decreasing sequence of the sums

$$\sum_j Q_{ij}^n$$

Thus these sums tend to 0 as $n \to \infty$. From this it follows that $Q_{ij}^n \to 0$ as $n \to \infty$, as each of these is non-negative. This proves the element-wise convergence stated in the lemma.

C. COALESCING STATES

We may wish to reduce a large set of states to a smaller number, for instance to define an alternative model. This appendix discusses the conditions under which this simplification may be performed: states can be grouped together (while preserving certain properties) provided they share next-state transition probabilities. This requirement is similar to the grouping property of Statecharts, that states non-trivially grouped together share next-state transitions.

Given a probability transition matrix P, we wish to find a smaller matrix with equivalent properties, so we can use smaller Markov models and obtain the same results. We shall do this by merging two sets of states together into a single state, and call the new probability transition matrix P^*.

What are the conditions these merged states must satisfy, and what is the appropriate way of calculating P^* from P?

Since the allocation of the N state numbers is arbitrary, we can exchange rows and columns in P so that the states to be considered for merging are adjacent. If the respective state occupancy probabilities of the two states are a and b, then the complete state probability vector can be written $(a \;\; b \;\; C)$, where C is a vector.

Now let $(a \;\; b \;\; C)\cdot P = (a' \;\; b' \;\; C')$. Since the probabilities are independent, we require:

$$(a+b \;\; C)\cdot P^* = (a'+b' \;\; C')$$

Write out P and P^* as conformant block matrices (so $p_{31},\ p_{32},\ p_{21}^*$ are column vectors; $p_{13},\ p_{23},\ p_{12}^*$ are row vectors; $p_{33},\ p_{22}^*$ are square matrices; and the rest are 1×1 matrices):

$$P = \begin{pmatrix} p_{11} & p_{12} & p_{13} \\ p_{21} & p_{22} & p_{23} \\ p_{31} & p_{32} & p_{33} \end{pmatrix},\ P^* = \begin{pmatrix} p_{11}^* & p_{12}^* \\ p_{21}^* & p_{22}^* \end{pmatrix}$$

Multiplying out we obtain constraints:

$$\begin{aligned} p_{22}^* &= p_{33} \\ p_{21}^* &= p_{31} + p_{32} \\ p_{12}^* &= p_{13} = p_{23} \\ (a+b)p_{11}^* &= ap_{11} + bp_{21} + ap_{12} + bp_{22} \end{aligned}$$

The last constraint must hold for all a and b, so $p^*_{11} = p_{11} + p_{12} = p_{21} + p_{22}$. This appears to be a tiresome constraint: but since P is a probability matrix (all rows add to one), the condition is equivalent to the existing constraint $p_{13} = p_{23}$. Collecting the equations we have:

$$P^* = \begin{pmatrix} p_{11} + p_{12} & p_{13} \\ p_{31} + p_{32} & p_{33} \end{pmatrix}, \text{ provided } p_{13} = p_{23}$$

If either a or b is always 0, then the constraints are trivial. In other words if there are states that are not initially occupied and are never reachable (which $p_{31} = 0$ or $p_{32} = 0$ would imply), then they can be deleted.

The process of pair-wise grouping can be repeated, reducing any set of suitable states into a single 'super' state (and there is no need to first permute the states to start at 1 or be adjacent). In words, we can group any states into a single state provided only that all states in the group share identical transition probabilities *out* of the group — this is the $p_{13} = p_{23}$ constraint.

It may be more convenient to deal with frequencies rather than probabilities. For example, a system specification will typically give explicit state-to-state transitions, and 'summing over states' will then directly give counts of all out-transitions for all states under consideration. Since probabilities are relative counts, a reduced matrix can be obtained by adding the appropriate counts together and dividing through each row by its total.

The transformation of P to P^* preserves the probabilities and the results obtained from a Markov model, but with one proviso: since states have been merged, the Markov model no longer 'counts' transitions between those original states.
